ABSTRACT

**Background:** To describe our experience to address lower eyelid lateral fat pocket through an upper eyelid approach.

**Methods:** Retrospective analysis of patients undergoing debulking of lower eyelid lateral fat pocket through an upper eyelid approach at Jules Stein Eye Institute by one surgeon (RAG) between 2006 and 2008. Concomitant surgical procedures were recorded. Preoperative and postoperative photographs at the longest follow-up visit were analyzed.

**Results:** Total of 15 patients (25 eyelids) underwent successful lower eyelid lateral fat pocket debulking through the upper eyelid. There were 12 males and 3 females, with mean age of 60 years old (range, 50-80 years old). 5 patients had prior history of lower eyelid blepharoplasty with residual prominent lower eyelid lateral fat pocket. Minimum follow-up time was 4 months (mean 6 months; maximum 1 year). Concomitant upper eyelid blepharoplasty was performed in 13 patients, while minimal incision lateral canthoplasty through the same upper eyelid incision was performed in 14 patients. There were no complications and no re-operations.

**Conclusions:** Debulking of lower eyelid lateral fat pocket through an upper eyelid approach can safely and effectively address this often hidden fat pocket. It may be ideal for those patients (usually older males) with only prominent lower eyelid lateral fat pocket, upper eyelid dermatochalasis, with or without lateral canthal laxity.
Transcutaneous lower blepharoplasty addresses excess skin, muscle, and fat through an infraciliary cutaneous incision. This approach offers excellent exposure to the fat pads; however, violation of the orbital septum may result in postoperative lower eyelid retraction, with resultant aesthetic disfigurement as well as exposure keratoconjunctivitis.\(^1\) Transconjunctival approach lower blepharoplasty avoids violation of the orbital septum, which may produce less postoperative eyelid retraction.\(^2\) However, the latter approach can lead to inadequate fat removal, especially from the often hidden lateral lower eyelid fat pocket, due to limited exposure.\(^3\)

Herein, we describe our experience to address lower eyelid lateral fat pocket through an upper eyelid approach, and discuss its advantages, which includes patients with only prominent lateral fat pocket, upper eyelid dermatochalasis, with or without lateral canthal laxity.

**Methods**

The charts of all patients undergoing debulking of lower eyelid lateral fat pocket through an upper eyelid approach at Jules Stein Eye Institute by one surgeon (RAG) between 2006 and 2008 were reviewed. Concomitant eyelid/orbital surgical procedures were recorded. Patients without digital preoperative and postoperative photographs for review were excluded.

Preoperative and postoperative photographs at the longest follow-up visit were analyzed. All photographs were obtained using a standardized technique in the frontal position with the eyelids open and facial muscles relaxed. Blind observers analyzed the photos.

**Surgical Technique**

All surgeries were performed under monitored anesthesia care along with local injection of lidocaine 2% with epinephrine. A limited lateral (Figure 1) or standard upper eyelid crease incision (Figure 2) was performed. The latter was performed if the patient was undergoing concomitant upper eyelid blepharoplasty. Through the lateral extent of the incision, blunt and sharp dissection, using Stevens
scissors, exposed the lateral canthal tendon and orbital rim. The inferior lateral canthal tendon fibers were released in those requiring concomitant lower eyelid tightening. The Eisler’s fat pad was preserved if possible. Then, the lower eyelid lateral fat pocket was exposed using blunt and sharp dissection to release septa. Using Senn retractor and gentle digital pressure on the globe helped in prolapsing the hidden fat pocket into view. The fat pocket was then debulked, using either Stevens scissors or monopolar cautery, as necessary.

Results

Total of 15 patients (25 eyelids) underwent successful lower eyelid lateral fat pocket debulking through the upper eyelid, with quick recovery. Minimum follow-up time was 4 months (mean 6 months; maximum 1 year). There were 12 males and 3 females, with mean age of 60 years old (range, 50-80 years old). 5 patients had prior history of lower eyelid blepharoplasty with residual prominent lower eyelid lateral fat pocket.

Concomitant upper eyelid blepharoplasty was performed in 13 patients, while minimal incision lateral canthoplasty through the same upper eyelid incision was performed in 14 patients. A representative case is shown in Figure 3. There were no complications or re-operation.

Discussion

The lower eyelid preaponeurotic fat is divided into 3 compartments. The medial and central fat pockets are separated by the inferior oblique muscle while the arcuate expansion divides the central from the lateral fat pocket. This lateral fat pocket is usually smaller and deeper than the others. In addition, it contains more septa than the others, which makes it less likely to herniate anteriorly. It is the hardest pocket to expose during transconjunctival lower blepharoplasty and it is often missed during surgery, only to protrude again after the patient is vertical and healing has occurred and swelling has subsided.3
Transcutaneous and transconjunctival approach lower blepharoplasty have their advantages and
disadvantages. Of note, as alluded to earlier, the often hidden lower eyelid lateral fat pocket can be
missed through this approach. The upper eyelid approach effectively and efficiently addressed the lower
eyelid lateral fat pocket without complications in all of our patients. The technique of removing the lateral
lower eyelid fat pad via the upper eyelid was first described by Glen Jelks. We used our modified
method in our selected patients because they only had protrusion of the lateral fat pocket, either genetic or
because this fat pocket was inadequately debulked during prior lower eyelid blepharoplasty. Furthermore,
far majority had upper eyelid dermatochalasis and mild to moderate lateral canthal laxity that needed to
be addressed as well. These patients tended to be male and older. They underwent standard upper eyelid
blepharoplasty. To correct the lateral canthal laxity, they underwent minimal incision canthoplasty
through the upper eyelid incision using a percutaneous approach (OPRS, in press), which is different but
analogous to that described by Glen Jelks.

The inferior lateral canthal tendon fibers may have to be released in our technique in order to
better expose the lateral fat pocket (Figure 1c). Most of our patients were older with lateral canthal laxity,
therefore they benefited from this step along with lateral canthal tightening after completion of the fat
debulkling (Figure 3). It is important to note that the lateral lower eyelid fat pocket is distinct from the
Eisler’s fat pad, which is distinct from the lateral extension of the preaponeurotic fat pocket of upper
eyelid (Figure 4). Eisler’s fat pad is a small fat situated between the orbital septum anteriorly and
superiorly, the lateral canthal tendon posteriorly and nasally; the lateral orbital rim temporally, and the
zygoma inferiorly (Figure 4). It does not require removal during blepharoplasty.

In summary, debulking of lower eyelid lateral fat pocket through an upper eyelid approach can
safely and effectively addresses this often hidden fat pocket. It may be ideal for those patients (usually
older males) with only prominent lower eyelid lateral fat pocket and upper eyelid dermatochalasis.
However, it can also be utilized along with the transconjunctival approach to address the often hidden and
difficult to access lateral fat pocket. It is also useful for patients with prior history of failed lower eyelid
blepharoplasty with remaining prominent lower eyelid lateral fat pocket. This technique can be combined with lateral canthal tightening through the same surgical incision. Knowledge of the anatomic relationship between the upper eyelid, lower eyelid, lateral canthus and orbit is important to avoid unnecessary damage when using this technique. The Eisler’s fat pad should be preserved if possible.
